ABSTRACT
Experimental measurement can be made only of inlet and outlet global temperature of plate heat exchanger (PHE), therefore the temperature profile along of a PHE is hardly ever known. The goal of this work was to evaluate the influence of a non-Newtonian behavior of pectin solution in the temperature response curves along of the PHE. The results were obtained using a simulation codified in Matlab 6.1 software. The response curves resulted from the simulations were fitted to models for identification and characterization of the system linearity. The result shows a clear non-linear behavior of the response curves along the PHE.

Keywords: plate heat exchanger; simulation; pectin; control.

NOMENCLATURE
I rate flow product disturbance, 45.5 kg/h
j number of channels
k number of channels subdivisions
K consistency coefficient, dimensionless
Kp static gain parameter, °C.h/kg
n flow behavior index, dimensionless
R² coefficient of determination, dimensionless
t time, min
T temperature, °C
X pectin concentration, (w/w)

INTRODUCTION
Considering the fact that most fluid food presents a non linear behavior, the knowledge of the internal dynamic behavior and the identification of the control parameters along the channels of the plate heat exchanger (PHE) are essential because it allows visualization and better understanding of the control process.

Many studies were carried out addressing transient shell and tube heat exchanger, whereas only a few investigations are found for PHE, e.g. a simulation of a transient response of a multipass PHE developed by Das and Murugesan (2000) and an experimental and analytic study of a PHE by Masubuchi and Ito (1977).

Some problems arise when carrying out experimental tests in PHE. One of them is that it is only possible to measure the inlet and outlet global temperatures and therefore the temperature profile along the PHE is hardly ever known (Rene et al., 1991).

From a process point of view, the working fluids in a food industry are very complex and the knowledge of temperature profile along the PHE is very important, since it allows the evaluation of the effect of a specific local temperature in changes of the physical and rheological properties and in the process quality of fluid food. Excessive heating, even for a short time, can affect food quality and its nutritious properties.

The scope of this work was to study the behavior of the temperature response curves of the product along the PHE and to find the best control parameters by mean of fitting models. Modeling and simulation of a PHE were used as the base for all these studies. The modeling considers the
influence of the rheological properties. The flow
behavior index and the consistency index are
assumed dependent on the temperature and fluid
concentration. Rheological empiric models were
used in the simulation of the pectin solution heat
process.

The response curves were obtained after
disturbance in the product flow rate. Different
models were evaluated to identify the dynamic
behavior of the control parameters along the PHE.

EXPERIMENTS

The PHE dynamic simulator was codified
by Berto and Silveira (2003) and the mathematical
modeling was based on the assumptions of Sharifi
et al. (1995) and Rene et al. (1991). The model
describes a transient process from energy balance
equations and uses the finite difference method for
the numerical calculations of the fluid temperature.

The temperature profile along the PHE was
evaluated for a pectin solution 2% (w/w). The
rheological properties of the pectin solution were
experimentally measured by Marcotte et al. (2001)
and the pectin solution was described by power law.

The values of the consistency coefficient
\( K \) and the flow behavior index \( n \) were fitted to
a fluid concentration \( (X) \) and temperature \( (T) \)
dependent function, showed in Eqs. (1) and (2). The
adjustment was carried out using the software
STATISTIC 5.0 and the Quasi-Newton parameter
estimation method.

\[
K = \exp \left( \frac{42198.8}{T} \right) \exp(0.93.X) \quad (1)
\]

\[
n = 18.3 \exp \left( \frac{-11.10}{T} \right) \exp(-0.01.X) - 16.80 \quad (2)
\]

Figure 1 shows a representation of the PHE
used in the simulation. The PHE presents eight
channels, which are subdivided into six equal parts (k).

In order to evaluate the behavior of the heat
exchange by the temperature profile in each
channel subdivision along a PHE, a step
disturbance of 45.5 L/h was imposed to the system
rate flow, in the pectin solution flow rate.

The temperature response curves of the
product were fitted to different linear equations as:
first order equation, first order with dead time, and
second order equation. For the adjustment of the
second order equation, the best case for the
damping factor between \( 0.8 < \zeta < 1.2 \) and \( \zeta = 1 \) was
evaluated.

The parameters of the equations were
obtained by means of a non-linear data fitting using
a Newton-Gauss Method, available in the software
Matlab 6.1. The parameters were obtained for all
channels (j) and channels subdivisions (k).

Figures 3-6 were plotted to verify the
linearity of the product temperature in different
positions of the PHE (channels 1, 3, 5 and 7), which
show the behavior of the response curves. Each
channel presents six temperature profiles that
correspond to the subdivision of the channels (k).
RESULTS AND DISCUSSION

Model Fitting for Identification of the Dynamic System Behavior

The temperature response curves of the product, obtained by means of the process simulation, presents form of ‘S’. Figure 2 shows the adjustments that were carried out for the response curves in the PHE outlet.

Once all the response curves of the process were best fitted ($R^2 > 0.9$) by the second order equation with the damping factor ($\zeta = 1$), this behavior was considered representative of the process.

The parameters $\tau$ and $K_p$ were fitted to the second order model with $\zeta = 1$, as shown by Eq. (3):

$$\delta T(t) = K_p \left( 1 - \left( 1 + \frac{\delta \theta}{\tau} \right) e^{-\frac{\delta \theta}{\tau}} \right)$$  \hspace{1cm} (3)

Response curves

Figures 3-6 present the response curve for each channel and was obtained by the ratio between the temperature difference and the disturbance value versus the time difference.

The temperature profile of the pectin solution 2% (w/w) of concentration, for the four product channels (1, 3, 5 and 7) are showed in Figs. 3-6, where is can be seen that each channel presents a transient behavior of the product temperature in each channel subdivision (k) in six different response curves (k1 to k6), in the direction of the product flow rate. It is important to observe the direction of the product path as showed in Fig. 1.

Evaluating Tabs. 2 and 3 and Figs. 3-6 it is possible to verify the growth of the static gain parameter $K_p$ along the PHE, along the channel and in its subdivisions, showing the increase of the static gain parameter.

Figure 3. Temperature response curves of the product for channel 1 after step disturbance in the pectin flow rate.

Figure 4. Temperature response curves of the product for channel 3 after step disturbance in the pectin flow rate.
Table 2 shows that the static gain parameter $K_p$ presents a constant growth with channel direction as channel subdivision, in the path of the product flow. The direction of the product flow is indicated in Tabs. 2 and 3.

The evaluation of the behavior along the PHE can be helped by observing Tab. 3, where the time constant shows a tendency of growth after the first channel, therefore the product requires more time to reach the steady state.

**CONCLUSIONS**

Through the temperature profile along the PHE it is possible to know the dynamic behavior of the system and to verify the strong non-linearity of the parameters $K_p$ and $\tau$ with relation of the channels and its subdivisions.

For each point along the PHE, there are different values for the second order model parameters, and this transient behavior indicates the need of tuning the controller to take into account these non-linearities of the process.

The knowledge of the behavior of the product along the PHE and the use of an adequate tuning is crucial in the food industry process. This study is fundamental in product quality control, since the use of an inadequate tuning, that does not consider the non-linearities of the process, can have a negative influence on food safety and on the sensorial qualities of the final product.
